Lineages, splits and divergence challenge whether the terms anagenesis and cladogenesis are necessary

Received 3 June 2015; revised 22 July 2015; accepted for publication 22 July 2015

Using the framework of evolutionary lineages to separate the process of evolution and classification of species, we observe that ‘anagenesis’ and ‘cladogenesis’ are unnecessary terms. The terms have changed significantly in meaning over time, and current usage is inconsistent and vague across many different disciplines. The most popular definition of cladogenesis is the splitting of evolutionary lineages (cessation of gene flow), whereas anagenesis is evolutionary change between splits. Cladogenesis (and lineage-splitting) is also regularly made synonymous with speciation. This definition is misleading as lineage-splitting is prolific during evolution and because palaeontological studies provide no direct estimate of gene flow. The terms also fail to incorporate speciation without being arbitrary or relative, and the focus upon lineage-splitting ignores the importance of divergence, hybridization, extinction and informative value (i.e. what is helpful to describe as a taxon) for species classification. We conclude and demonstrate that evolution and species diversity can be considered with greater clarity using simpler, more transparent terms than anagenesis and cladogenesis. Describing evolution and taxonomic classification can be straightforward, and there is no need to ‘make words mean so many different things’.

THE EVOLUTIONARY PROCESS AND SPECIATION

In this review, we assess the terms ‘anagenesis’ and ‘cladogenesis’ because they epitomize the barrier to communication that results from the conflation of the process of evolution and our interpretation of life using taxonomy. Opinion may vary regarding the future application of the terms, but we illustrate how the current usage is vague, inconsistent and therefore unhelpful. We conclude that communication across disciplines could be improved by avoiding these terms or acknowledging limitations, and we demonstrate how this can be achieved.

An evolutionary lineage, or line of descent, is the inherent product of evolutionary units replicating in generations over time, and consequently it is a universal feature of all biologically evolving systems (Cutter, 2013). A ‘species’ is therefore always a taxonomic description of an arbitrarily delineated segment of an evolutionary lineage in time (de Queiroz, 1998, 2007; Sites & Marshall, 2003; Podani, 2013; White, 2013). For different organisms the delineated region will vary in size, scale and duration in time depending upon the nature of the taxonomic paradigm employed, the availability of data (past and present) and the hypothesis under investigation (de Queiroz, 1998, 2007; Sites & Marshall, 2003; White, 2013). However, although a species is artificial, it remains a hypothesis based on empirical observations of an evolutionary lineage (Barraclough & Nee, 2001; de Queiroz, 2011; Strotz & Allen, 2013; Dyne- sius & Jansson, 2014; see Fig. 1 for an explanatory metaphor). Philosophically this means that we treat a species as a mental concept based on the material reality of evolutionary lineages (see discussion in Mahner, 1993). Recognizing the consensus of evolutionary lineages is hugely beneficial because

conflicting species concepts, such as those based on reproduction or morphology, become compatible through accommodation of the evolutionary process (Wei, 1987; de Queiroz, 1998; Cohan, 2002; Cutter, 2013; Ezard, Thomas & Purvis, 2013; Podani, 2013; White, 2013).

Importantly the lineage perspective helps us reconsider the process of evolution over long time periods. For instance, because evolutionary lineages are continuous in time, those lineages represented by taxonomic units such as species can be subdivided into further lineages that reflect classification of subspecies, varieties or metapopulations that encompass intraspecific variation (Mallet, 2008a; Dynesius & Jansson, 2014). This emphasizes that there is no break in the process of evolution from the lineages studied using population genetics (‘microevolution’) and the lines of descent studied during ‘macroevolutionary’ research (Barraclough & Nee, 2001; Crampton & Gale, 2005; Cutter, 2013). Likewise, the fact that there is no convenient origination point (aside from the origin of life) to which a lineage can be traced reminds us that our ‘start point’ for any investigation of a species, population or a fossil continuum is itself an arbitrary date along a line of descent (Ezard et al., 2012).

The evolutionary lineage perspective, with species acknowledged as arbitrary partitions, also allows us to disentangle the different concepts commonly considered under speciation (follow Fig. 1). ‘Divergence’ is the accumulation of genetic or phenotypic differences among evolutionary lineages over time that results in distinct variation (Abbott et al., 2013; Sætre, 2013; Dynesius & Jansson, 2014). Divergence is simply a temporal function recording the inevitable change that accrues between partitioned groups of individuals. It results in genetic and phenotypic difference (measured as diversity or distance), typically estimated at the tips of branches in phylogenetic trees. ‘Lineage-splitting’ (or lineage-branching) is defined by the cessation of gene flow between groups of individuals, and therefore it marks the division of an evolutionary lineage into two or more further lineages (Dynesius & Jansson, 2014). Importantly, splitting does not guarantee divergence between lineages (Heelemann et al., 2014), although increased divergence can be facilitated by reduced gene flow. Divergence is studied using lines of descent through time (lineages), but it is not defined by lineage-splitting. A reproductively isolated population can be a representative sample of the original metapopulation, and likewise a connected population within a metapopulation may be highly divergent. ‘Hybridization’ (or reticulation) is the inverse process of splitting, where gene flow is re-established between lineages intermittently or permanently (see Fig. 1D).

‘Speciation’, like ‘species’, is an arbitrary taxonomic classification of the evolutionary process. ‘Speciation’ refers to an arbitrarily selected lineage-split that is deemed to represent the birth of a new
species. It is arbitrary because the identification of a new species depends upon particular diagnostic thresholds (relative to organisms, scale of observation, data, etc.), which inherently depends upon divergence rather than splitting. Species origination is an epistemological dilemma – is a species classified when a lineage is distinct (but not necessarily separated by gene flow), or when a lineage is separate (but not necessarily distinct)? If a population is morphologically derived with respect to its ancestral population, should it be classified as a separate species based on such difference even if lineage-splitting is not evident? The fact that the answer differs between investigations reflects that the choice is ultimately subjective. So, ‘divergence’ is an increase in difference among evolutionary lineages, ‘splitting’ is the cessation of gene flow between lineages, and ‘speciation’ is the origination of a new species that ideally reflects both divergence and splitting. Divergence and splitting directly describe empirical change among evolutionary lineages, whereas species and speciation are ad hoc classifications applied to interpret the process (see difference between Fig. 1A, B).

The distinction of process and interpretation is advantageous as it recognizes, along with traditional splitting and divergent factors such as isolation and niche separation (Barraclough & Nee, 2001; Mallet, 2008b; Maan & Seehausen, 2011), that hybridization of lineages below the species level affects rates of species formation (Abbott et al., 2013; Dynesius & Janson, 2014). The distinction also reminds us that there is no inherent reason why an increase in the divergence rate, or the molecular evolutionary rate, should incur an increase in the speciation rate (Pennell, Harmon & Uyeda, 2014b). Although there may be a positive correlation between these rates (Webster, Payne & Pagel, 2003; Lanfear et al., 2010; Dowle, Morgan-Richards & Trewick, 2013; Vendetti & Pagel, 2014), a split can only be classified as the generation of a new species when a lineage-segment is assigned to the species level. This definition of ‘speciation’ is also preferable as it retains the pure meaning of a new species being generated (de Queiroz, 1998), rather than a technical process that reflexively restricts the meaning of ‘species’. A review of the lineage framework is presented Figure 1 as a metaphor and Table 1 provides a glossary of terms.

**AMBIGUITY OF ANAGENESIS AND CLADOGENESIS**

Although the context of evolutionary lineages clarifies the relationship between the evolutionary process and the classification of species, confusion persists due to the ambiguous usage of some terms. In particular, we observe that the terms of ‘anagenesis’ and ‘cladogenesis’ are frequently used in discussions of evolution and speciation despite the definition and application of the terms varying widely (e.g. Axe et al., 2013; Hunt, 2013; Strotz & Allen, 2013; Patiño et al., 2014; Valente, Etienne & Phillimore, 2014). The terms have generated criticism (e.g. Dubois, 2011), and definition can be vague (e.g. Patiño et al., 2014) or even absent (e.g. Drew & Barber, 2009). This is alarming as the terms are central to many neo- and palaeobiological studies (e.g. Drew & Barber, 2009; Haile-Selassie & Simpson, 2013; Hunt, 2013; Strotz & Allen, 2013; Patiño et al., 2014).

Confusion is in part due to the changing usage of anagenesis and cladogenesis over time (Rensch, 1929, 1959), akin to the conceptual evolution of ‘punctuated equilibrium’ (Eldredge & Gould, 1972; Lieberman & Eldredge, 2014; Pennell, Harmon & Uyeda, 2014a). Anagenesis and cladogenesis were originally coined to differentiate between evolutionary change that leads to the classification of higher taxonomic units such as families (called ‘transspecific evolution’) and ‘narrow-sense’ change at the level of species (‘intraspecific evolution’) (Rensch, 1929, 1959; Glass, 1949). Both terms considered speciation (assuming divergence as a proxy) and were not differentiated by it, nor were they mutually exclusive (Simpson, 1949). Specifically, anagenesis considered a believed trend for increasing complexity in further derived lineages (‘higher evolved organisms’), typically considering morphology (Rensch, 1929, 1959). Cladogenesis was concerned with the evolution of clades – ‘broad’ branches that yielded significant taxonomic diversity (Rensch, 1929, 1959). Cladogenesis was treated as the breadth of an evolutionary tree and anagenesis was the height of branches (where increasing stature was increasing complexity) (Rensch, 1929, 1959). Soon after conception, the terms were applied directly to speciation (Simpson, 1949), and later were integrated with the monophyletic clad and grade concepts of Huxley (1957). Afterwards the terms were merged into the framework of ‘cladistics’ as exemplified by Henning (Mayr, 1973). Due to the mixing of terminology, ‘cladogenesis’ was inferred to reference the monophyletic branches used as units in cladistics, even though such ‘clades’ have an independent etymology (Cuénot, 1940).

Anagenesis and cladogenesis continue to be used differently by experts among fields. For instance in some biogeography studies, anagenesis is used to refer to founder effects and the formation of endemic species (Patiño et al., 2014; Valente et al., 2014). Similarly, some phylogeographical models refer to speciation caused by geographical mechanisms as cladogenetic events (Shaw et al., 2015). The discussion of punctuated equilibrium in particular has

<tr>
<td>Evolutionary lineage</td>
<td>A line of descent of evolutionary units (organisms, replicators). All evolutionary units belong to an evolutionary lineage, but our ability to identify particular evolutionary lineages depends upon the availability and scale of data. Evolutionary lineages are continuous through time and can be subdivided down to the level of individual replicators.</td>
<td>Process and pattern</td>
</tr>
<tr>
<td>Species</td>
<td>An arbitrary segment of an evolutionary lineage in time classified as a distinct species. Species can be delineated under many different protocols depending upon divergence-based factors such as the data available, studied organism (species criteria) and the hypotheses under investigation.</td>
<td>Classification</td>
</tr>
<tr>
<td>Divergence</td>
<td>The accumulation of genetic or phenotypic difference among evolutionary lineages over time that results in distinct variation. Divergence reflects the genetic or phenotypic diversity among lineages, but it does not necessarily require lineage-splitting. Difference can also be measured through time between ancestor and descendant populations.</td>
<td>Process</td>
</tr>
<tr>
<td>Lineage-splitting (or lineage-branching)</td>
<td>The cessation of gene flow between populations that causes an evolutionary lineage to divide into two or more. The point at which an interconnected gene pool splits in two. Lineage-splitting can be reversed via hybridization.</td>
<td>Process</td>
</tr>
<tr>
<td>Hybridization (or reticulation)</td>
<td>The re-establishment of gene flow between two evolutionary lineages. The inverse process of lineage-splitting. Hybridization can occur between distantly related lineages as well as recently split lineages.</td>
<td>Process</td>
</tr>
<tr>
<td>Speciation</td>
<td>Splitting of an evolutionary lineage arbitrarily classified to correspond with the designation of a new species. The origination of a species. The classification of a species often depends upon divergence-based factors such as the data available, studied organism (secondary species criteria) and the hypotheses under investigation.</td>
<td>Classification</td>
</tr>
<tr>
<td>Stasis</td>
<td>No significant deviation from an evolutionary state (genetic, phenotypic) over a period of time. Described character states are typically a mean as individuals vary. It reflects divergence that is minor, not sustained, or which does not accumulate. It is driven by stabilizing selection, frequency-dependent selection or selection conflict.</td>
<td>Hypothesis regarding process</td>
</tr>
<tr>
<td>Gradualism</td>
<td>A slow, continuous rate of evolutionary change. Some rate variation may occur but it is not overall significant. Originally coined by Hutton (1788), referring to the consistency of change in geology. Expanded by Lyell (1833), in response to Whewell (1831), to describe that the laws of nature (physics, biology) are unchanging, but the rates of geological preservation (e.g. sedimentation, erosion) are highly variable. Co-opted by Darwin (1859) to refer to a continuous rate of change during biological evolution rather than abrupt change.</td>
<td>Hypothesis regarding process</td>

</table>
confused the terms because anagenesis and cladogenesis have been conflated with variation in rates of molecular evolution, speciation and diversification (Benton & Pearson, 2001; Bokma, 2008). Mistakenly, anagenesis is connected or synonymized with phyletic gradualism, gradualism or even stasis (Chaline, 1977; Bokma, 2002; Mattila & Bokma, 2008; Pachut & Anstey, 2012; Lister, 2013; Pearson & Ezard, 2014), and cladogenesis with punctuated change (Bokma, 2002, 2008; Lister, 2013). Rates of speciation and cladogenesis are also incorrectly assumed to be equal (Pennell et al., 2014b). The two terms have even been referred to as ‘modes’ of evolution, suggesting that fundamental mechanisms are described (Pachut & Anstey, 2012; Strotz & Allen, 2013). The insight provided prompts us to question whether anagenesis and cladogenesis are necessary.

In palaeontology, usage is fairly consistent, with ‘cladogenesis’ typically defined as lineage-splitting (branching) (de Queiroz, 1998; Jackson & Cheetham, 1999; Catley, Novick & Shade, 2010; Aze et al., 2013; Bapst, 2013; Futuyma, 2013). Correspondingly, ‘anagenesis’ (or phyletic change) is treated as evolutionary change that occurs within a lineage (Johnson et al., 2012; Pachut & Anstey, 2012; Aze et al., 2013; Bapst, 2013; Futuyma, 2013; Strotz & Allen, 2013), between lineage-splits (e.g. Hunt, 2013; Lister, 2013; Van Bocxlaer & Hunt, 2013). This means that ‘anagenetic change’ is used to mean evolutionary change without lineage-splitting (Jackson & Cheetham, 1999; Catley et al., 2010; Johnson et al., 2012; Bapst, 2013).

Nevertheless, there is a strong tendency to link anagenesis and cladogenesis to speciation. Cladogenesis is commonly considered to be interchangeable with speciation; lineage-splits are assumed to represent the division of one species into two or more (Benton & Pearson, 2001; Mattila & Bokma, 2008; Drew & Barber, 2009; Hunt, 2013; Lister, 2013; Strotz & Allen, 2013; Dynesius & Jansson, 2014; Pearson & Ezard, 2014). In contrast, anagenesis generates conflict as to whether it is a form of speciation (e.g. Jackson & Cheetham, 1999; Catley et al., 2010; Podani, 2013) or is not (e.g. Bapst, 2013; Ezard et al., 2013; Lister, 2013; Strotz & Allen, 2013; Pennell et al., 2014a). Species can be argued to originate without lineage-splitting because the derived genotype or phenotype of a seemingly un-split lineage is taken to be significantly different from the ancestral state (Benton & Pearson, 2001; Catley et al., 2010; Podani, 2013). Such species are often referred to as ‘chronospecies’ (de Queiroz, 1998; Benton & Pearson, 2001; Haile-Selassie & Simpson, 2013; White, 2013). These anagenetically produced chronospecies are controversial as they are based on difference of form along a lineage rather than splitting or direct evidence of divergence; they are therefore based on relative character states and particular dates, which can be criticized as an especially arbitrary basis for species delineation (White, 2013, 2014; Vanderlaan & Ebach, 2014).

ARE ANAGENESIS AND CLADOGENESIS NECESSARY TERMS?

The varied usages of anagenesis and cladogenesis across biological disciplines is not ideal for clarity, and even the seemingly robust definitions used in palaeontology generate ambiguity between the evolutionary process and species classification. However, the context of evolutionary lineages allows us to disentangle the different concepts conflated under anagenesis and cladogenesis. The insight provided prompts us to question whether anagenesis and cladogenesis are necessary.

NOT ALL LINEAGE-SPLITS ARE INFORMATIVE FOR STUDYING LONG-TERM EVOLUTION

While lineage-splits and evolutionary change between them function as identifiably different concepts, the
The descriptive value of this distinction depends upon observation. Problematically, splits are ubiquitous during evolution but not all splits are fixed, and not all splits are of interest. Breaks in gene flow (splits) result in population structuring (Méndez, Tella & Godoy, 2011; Abbott et al., 2013; Helemann et al., 2014), and can persist for few or many generations (Bhat et al., 2014). Breaks in gene flow are not necessarily absolute nor permanent; two allopatric populations may reconnect (Sternkopf et al., 2010; Abbott et al., 2013), as can so-called incipient species (Bhat et al., 2014), and apparently distinct species can successfully hybridize when opportunity arises (Shiga & Kadono, 2007; Dubois, 2011; Mráz et al., 2012; Pruvost, Hoffman & Rey'er, 2013), even millions of years after lineage-splitting (Mallet, 2007; Rothfels et al., 2015). This means that many lineage-splits are masked during evolution and it highlights the importance of hybridization during evolution (Mallet, 2008a; Abbott et al., 2013; Dynesius & Jansson, 2014). Ultimately, gene flow and lineage evolution are also terminated by extinction. Depending upon its frequency, population extinction can generate many splits as it prevents interbreeding among family lines and between metapopulations. This means that lineage-splits are prolific over the course of evolution. However, extinction also erases evidence of lineage-splits because descendants are not available for sampling, which yields long naked branches in molecular phylogenetic reconstructions (Crisp & Cook, 2009; Grandcolas, Nattier & Trewick, 2014). With so many splits occurring and being obscured during evolution it is impossible for all to be identified, and therefore the classification of anagenesis and cladogenesis also becomes untenable. Similarly, partitioning events of divergence with lineage-splits (if they correspond at all) faces the same problem of discrimination.

**IDENTIFYING LINEAGE-SPLITS REQUIRES GENETIC DATA**

The differentiation of anagenesis and cladogenesis via lineage-splitting is popular in palaeontology (e.g. Jackson & Cheetham, 1999; Benton & Pearson, 2001; Crampton & Gale, 2005; Aze et al., 2013; Ezard et al., 2013; Pearson & Ezard, 2014). Using lineage-splits to distinguish anagenesis and cladogenesis creates a quandary for palaeontology, however, because phylogeny can only be inferred from observations of morphology. Analysis of morphological data alone, with no knowledge of gene flow, means that difference must be used to define cladogenesis instead of lineage-splitting. Sequential changes in morphology along a time series, ideally with constrained geography and sufficient sampling (e.g. Pearson & Ezard, 2014), provide a proxy for an evolutionary lineage (path of genetic inheritance and changing phenotype of a lineage). However, the degree of difference (phenotypic or genetic) is an inadequate proxy for the timing or position of lineage-splitting itself (see Fig. 2A).

---

**Figure 2.** A, evolutionary lineages and measures of difference. (a) Difference between contemporaneous extant populations (1 and 2) that belong to different lineages. (b) Difference between contemporaneous fossil populations. In this example the samples (3 and 4) belong to the same lineages as in (a) and are therefore part of the same divergence process. (c) Difference between two populations from different times on the same evolutionary lineage. This is an ancestral/derived relationship. In this example Sample 1 is extant and Sample 3 is fossil, but both samples could be fossil populations. Such populations could be treated as chronospecies, as is common in comparisons between fossil samples of different age that are presumed to belong to the same single lineage. (d) Difference between two populations (4 and 5) from different times on different evolutionary lineages. In contrast to (c) these are not ancestral and derived representatives of the same lineage, but in the absence of genetic information it would be impossible to know this. B, identifying lineage-splits without genetic data. Morphological data alone are insufficient to demonstrate lineage-splitting. Morphological difference observed in the fossil record between $T_1$ and $T_2$ does not necessarily correspond to a lineage-split (although it does provide a testable hypothesis), and divergence may have occurred before or after any existing split within the intermediate time period.
In palaeontology, difference fails to accurately predict the position of lineage-splits because morphology may diverge before or after a true lineage-split (Fig. 2). Consider, for example, that many species defined by clear genetic cohesion exhibit differing degrees of morphological variation (Blomster, Maggs & Stanhope, 1999; Calsbeek, Smith & Bardeleben, 2007; Hopkins & Tolley, 2011), and that many morphologically cryptic species comprise genetically distinct lineages (e.g. Trewick, 2000; Feldberg et al., 2004; Herbert et al., 2004; Heulskens et al., 2013; see Fig. 2B for an illustration). Simply, without genetic data it is not possible to distinguish within-lineage and between-lineage morphological variation (Van Bocxlaer & Hunt, 2013). Increasing evolutionary time can provide confidence that divergent morphology approximates increasingly well with lineage-splitting, but this is mostly due to lineage-sorting and extinction. Even when divergence is simultaneous with a geological mechanism such as sea-level change, it cannot be used to precisely estimate when a lineage-split may have occurred as such geographical changes can exist for thousands of years (Page & Hughes, 2014). It remains impossible to be certain of when a split occurred and therefore it is difficult to precisely estimate periods of anagenetic and cladogenetic change using morphological data alone (Crampston & Gale, 2005). We agree with Bapst (2013) that it is important to distinguish lineage-splitting, morphological divergence and speciation in palaeontology.

SPECIATION IS ARBITRARY

Anagenesis and cladogenesis could be distinguished by classifying lineage-splits to be above or below the species level. This would allow us to ignore the majority of splits that occur during evolution that may not contribute to long-term evolutionary patterns. This would automatically mean that only cladogenesis increases species diversity (Ezard et al., 2012; Strotz & Allen, 2013), whereas anagenesis results in static species diversity (Ezard et al., 2012; Haile-Selassie & Simpson, 2013). Unfortunately this strategy is both circular and arbitrary. The distinction of species level lineages can only be relative as it is dependent upon the studied organism, data available and hypothesis under investigation (Ezard et al., 2013; Haile-Selassie & Simpson, 2013). Even within a single genus, where taxonomic species delineation may have reached a consensus that permits a consistent definition of anagenesis, this approach would not lend itself to comparison across the tree of life. It may be helpful for researchers to use anagenesis and cladogenesis in this relative manner based on the lineage level or evolutionary persistence, but the limitations must be acknowledged.

Crucially, the distinction is also flawed because it fails to acknowledge that species are arbitrary and that speciation is an artificial concept established on a particular taxonomic paradigm. As species are arbitrarily classified segments of evolutionary lineages they are not discrete states of evolution. At any point a lineage segment can be revised to occur above or below the species level, and correspondingly splits could be reclassified from anagenesis to cladogenesis or vice versa. This type of reciprocal illumination means that the criteria used to define the pattern and process are conflated. Likewise, hybridization can cause lineages to regress below the species level (e.g. Abbott et al., 2013; Bhat et al., 2014; Dynesius & Jansson, 2014), and, because the boundaries of a species do not strictly depend upon lineage-splitting (e.g. species with hybridizing boundaries, ring species, chronospecies), speciation is not a definitive process with a beginning and end. There is no consistency between organisms for distinguishing particular splits as speciation, and there is no agreed point of complete speciation. This already appears to be recognized by authors who have adopted the terms ‘pseudospeciation’ and ‘pseudoextinction’ to describe divergence in the absence of known splitting (e.g. de Queiroz, 1998; Ezard et al., 2012, 2013; Bapst, 2013; Haile-Selassie & Simpson, 2013; Podani, 2013). Species-based definitions of anagenesis and cladogenesis are also post hoc and cannot be applied to currently evolving lineages (i.e. all living lineages) because we cannot predict future splitting, divergence or hybridization.

SPECIATION CONSIDERS MORE THAN LINEAGE-SPLITTING

Some lineage-splits are biologically significant because they represent genuine cases of ‘instantaneous speciation’. This can occur, for example, via karyotype changes (Moritz & Bi, 2011), the evolution of parthenogenesis (Abe, 1986), or androgenesis (Scali, Milani & Passamonti, 2012). These scenarios allow neat differentiation of anagenesis and cladogenesis in a species-based manner; however, the majority of species appear to have emerged in a less abrupt manner (Rymer et al., 2010; Claramunt et al., 2012; Near et al., 2012). Most ‘speciation’ is associated with divergence rather than lineage-splitting – new species are usually characterized by unique, identifiable genetic or phenotypic variation compared with related populations (Bapst, 2013). Most often, a particular lineage-split is likely to be merely one step during the change identified as speciation. Focusing on lineage-splitting also distracts from the importance
of lineage hybridization during speciation (Mallet, 2008a, b; Abbott et al., 2013; Sætre, 2013; Dynesius & Jansson, 2014). Even discrete changes related to instantaneous speciation can also be caused by introgression via ploidy changes associated with hybridization (Mallet, 2007; Mráz et al., 2012), and the evolution of reproductive systems such as hybridogenesis (Dubois, 2011; Pruvost et al., 2013).

Even when a lineage-split does represent an abrupt evolutionary change or innovation, many resulting lineages swiftly go extinct. For numerous reasons, systematics generally pays little attention to describing a unique lineage, even if it formed via a single split, unless it persists for a significant length of evolutionary time. The relevance of persistence through time is relative to the studied organism and is dependent upon evolutionary rate estimates that embroil further problems such as gene tree heterogeneity (McCormack et al., 2010; Cutter, 2013), and requires accurate estimations of extinction rates that might be intractable (Barraclough & Nee, 2001; Quental & Marshall, 2010; Morlon, Parsons & Plotkin, 2011). For example, a new viral strain may be classified as a species-equivalent within a matter of months, whereas a reproductively isolated group of animals following a karyotype change is unlikely to be classified as a species for thousands or millions of years (Morgan-Richards, Trewick & Wallis, 2001).

Species classification is concerned with divergence, hybridization, extinction and informative value as much as splits and monophyly. Overall, it is unhelpful to synonymize cladogenesis (and lineage-splitting) with speciation.

**Understanding evolution without anagenesis and cladogenesis**

To illustrate the frequent redundancy of the terms ‘anagenesis’ and ‘cladogenesis’, we rephrase excerpts from recent studies using fundamental concepts in evolution. In many cases abandoning the terms improves the clarity of reasoning and expression, making research more accessible, and in a few instances it reveals ambiguity or indicates areas for further research. When we replace the terms anagenesis and cladogenesis from recent publications it reveals differences in current usage that are clearly contradictory.

_Palaontology and phylogenetics_

‘A model was fit that allows estimation of anagenetic (within-lineage) evolution, cladogenetic (speciation) change and geographic variation within species.’ (Hunt, 2013).

A model was fit that allows estimation of lineage-splitting above and below the species level, and geographical variation within species. ‘The signal for anagenetic vs. cladogenetic change is subtle: it hinges upon whether the magnitude of divergence between species is more strongly correlated with elapsed time (as predicted by anagenetic change) or with the number of speciation events (as predicted by cladogenetic change) since their common ancestor.’ (Hunt, 2013).

The signal for phylogenetic gradualism vs. punctuated change is subtle: it hinges upon whether the magnitude of divergence between species is more strongly correlated with elapsed time (as predicted by phyletic gradualism) or with the number of speciation events (as predicted by punctuationalism) since their common ancestor.

[They assessed] the relative frequency of anagenesis (evolution within a single evolving lineage) and cladogenesis (lineage branching) in the production of new morphospecies. They conclude that anagenesis is much less prevalent than indicated in our phylogeny. (Aze et al., 2013).

[They assessed] the relative frequency of evolutionary change that does and does not generate a net increase in species diversity during the production of new morphospecies. They concluded that evolutionary change that did not lead to a net increase in species diversity was much less prevalent than indicated in our phylogeny.

**Biogeography**

The theory of “punctuated equilibrium” proposes that species change suddenly during short bursts associated with speciation (“cladogenetic change”). It is best exemplified on oceanic islands, where adaptive radiations have led to spectacular cases of endemic speciation... On islands, the gradual evolution of a new species from a founder event has been called “anagenetic speciation”. This process does not lead to rapid and extensive speciation within lineages, as adaptive radiation may do.’ (Patiño et al., 2014).

The theory of ‘punctuated equilibrium’ proposes that species change suddenly during short bursts associated with speciation. It is best exemplified on oceanic islands [sic], where adaptive radiations have led to spectacular cases of endemic speciation... On islands, following a population founder event new species can evolve gradually. This process does not lead to rapid divergence as adaptive radiations may do.

**Conclusion**

‘Anagenesis’ and ‘cladogenesis’ are vague and inconsistently defined terms in current research that have been conflated with other hypotheses (Rensch, 1929; Simpson, 1949; Jackson & Cheetham, 1999; Mattila

AMBIGUITY OF ANAGENESIS AND CLADOGENESIS

The most popular, robust definitions are based on the splitting of evolutionary lineages (Jackson & Cheetham, 1999; Catley et al., 2010; Bapst, 2013; Van Bocxlaer & Hunt, 2013), and most authors conflate lineage-splitting with speciation (e.g. Mattila & Bokma, 2008; Drew & Barber, 2009; Hunt, 2013; Dynesius & Jansson, 2014). This is problematic because lineage-splitting is prolific in nature and not all splits are of interest – especially when investigating evolution over long time periods. Splits are common due to population structuring and extinction, and hybridization and extinction mask and reduce the consequence of many splits. Species are arbitrary units, and therefore attempts to differentiate between lineagesplits above and below the species level are relative and dependent upon the studied organism, data available and hypothesis under investigation.

Studying change in species diversity over time is of immense value and is required alongside analysis of the evolutionary process. We emphasize, however, that conflating descriptions of the evolutionary process (lineages, divergence, splitting, hybridization) with taxonomy (species, speciation) does not benefit either line of investigation. Anagene
gesis and cladogenesis can remain useful terms if future definitions are aware of this separation, even if the terms are accepted to be relative to particular studied organisms. However, if this problem is ignored, anagenesis and cladogenesis will remain a barrier to communication across disciplines, and the terms shall remain replaceable with more fundamental, transparent concepts. Studies of evolution do not need to focus solely on identifying species level change.

ACKNOWLEDGEMENTS

We thank James S. Crampton, Simon F. K. Hills, Vaughan V. Symonds, Frank E. Anderson, David E. Penny, Mats Dynesius and anonymous reviewers for providing helpful comments and discussion. Thanks go to Anna-Sophie Roß for her help with German translation. This work was supported by the Royal Society of New Zealand Te Aparangi Marsden Fund grant (12-MAU-008).
